Abstract

Background: Intravascular large B-cell lymphoma (IVLBCL) is a rare type of non-Hodgkin's lymphoma (NHL) characterized by the selective growth of neoplastic cells within blood vessel lamina. The precise mechanisms responsible for this distinctive behavior are at the moment largely unknown. By the time of presentation, most patients have advanced, disseminated disease, and often the diagnosis is made at autopsy. Diagnosis requires skin, liver, lung, bone marrow, renal, meningeal, or brain vessel biopsy but is often made only when the illness has progressed or post mortem because early involvement of organs was not evident.

Discussion: We report a case of Intravascular lymphoma who presented as fever of unknown origin. In this case, initial laboratory test results were unremarkable. Computed Tomography of the chest and abdomen as well as bone marrow aspiration and biopsy were negative for malignancy. Patient developed neurologic symptoms and expired due to complications. Autopsy was done which revealed Disseminated Intravascular Diffuse Large B-cell Lymphoma.

Conclusion: Without treatment, intravascular lymphoma is rapidly fatal. Ante-mortem diagnosis is challenging and indefinable. A high index of suspicion followed by biopsy of the organs suspected to be involved, together with early institution of treatment are of utmost importance in approaching these kinds of patients.

Keywords: Disseminated; Intravascular; Lymphoma; B-Cell

Introduction

Intravascular lymphoma (IVL) is an uncommon subtype of lymphoproliferative disorder characterized by the proliferation of neoplastic cells within the lumen of small-caliber blood vessels [1]. This type of lymphoma was first reported in 1959 by Pflieger and Tappeiner in Germany as "angio-endothelioma-tosis proliferans systemisata" and was considered to be endothelial in origin. This disorder exhibits a life-threatening clinical course of a systemic disease, with predominant neurologic, hematologic, skin, bone marrow, and pulmonary involvement. The course and evolution are unfavorable due to aggressive behavior and late diagnosis. In recent years, the number of patients with IVL diagnosed antemortem has increased, mainly due to better knowledge of this disease [2]. The IVL diagnosis may be made by biopsies of compromised tissues or by random skin biopsy of visibly unaltered skin [3]. We describe the case of a 66-year-old white woman with IVL presenting as fever of unknown origin (FUO) of 1-year evolution and a progressive behavior with predominantly neurologic and pulmonary compromise.

A 66-year-old woman was admitted for fever and left hemiparesis. One year before, she had FUO and pericardial effusion with a pericardial biopsy showing unspecified chronic pericarditis. The patient continued with recurrent fever in the last 12 months. One day before admission, she developed left hemiparesis and was admitted to our institution. Physical examination on admission revealed fever (38–

38.5°C), skin pallor, and mild left hemiparesis. No lymphadenopathy, hepatosplenomegaly, cardiac murmurs, pulmonary abnormal sounds, or cutaneous lesions were present. Laboratory evaluations were: hemoglobin (Hb) 9.6 gr/dL with a mean corpuscular volume of 88 fl and reticulocytes of 1%. White blood cells were $4.7 \times 10^9/L$ (neutrophils 80%, lymphocytes 12%, and monocytes 8%) and platelet count $240 \times 10^9/L$. Serum C-reactive protein (CRP) was 8 mg/dl and the erythrocyte sedimentation rate was 129 mm/h. Serum AST and ALT was slightly elevated and serum lactic dehydrogenase (LDH) was severely elevated (1692 UI/L). Serum ferritin was 1650 mg/dl. The total serum protein was decreased, as were albumin and gammaglobulin, without paraprotein. Urinalysis was normal. Blood and urine cultures were negative. An HIV antibody test was negative, as were HBsAg, HCV, Epstein-Barr virus IgM, Huddleson test, VDRL, toxoplasmosis antibodies, cytomegalo-virus (CMV) antibodies, and CMV-polymerase chain reaction [4]. The antinuclear antibody test was negative, as were anti-DNA antibody, antineutrophil cytoplasmic antibodies, rheumatoid factor, antiphospholipid antibodies, cryoglobulins, and serum complement. A trans-esophageal echocardiogram, a computer tomography (CT) of the thorax, abdomen, and pelvis were normal, and a positron emission tomography (PET-CT) scan did not show abnormal images. An MRI showed multiple and bilateral ischemic brain images (Figure 1A, 1B). Cerebral spine fluid (CSF) cytology and flow cytometry examinations were normal. Bone marrow (BM) examination with immunohistochemistry and flow cytometry showed normal cellularity

without neo-plastic cells. Suspecting systemic vasculitis with central nervous system (CNS) compromise, 1000 mg/d IV of methylprednisolone for 3 doses was indicated. However, the patient continued with fever and worsening hemiparesis and she developed dyspnea with hypoxemia; a thoracic CT scan was performed showing bilateral consolidative images. Suspecting infectious pneumonia, antibiotic treatment was started without improvement and progressive hypoxemia developed. Cultures of blood, urine, and bronchoalveolar lavage fluid were negative. Due to progressive neurologic manifestations, pulmonary involvement, unremitting fever without evidence of infectious or immunologic disease, and persistently elevated serum LDH, an intravascular lymphoma (IVL) was suspected. To confirm this diagnosis, cutaneous random biopsies were made. These biopsies revealed atypical lymphocytes within the small vessels of the dermis and hypodermis. The immunophenotype was consistent with B cell phenotype, showing CD20, PAX5, and BCL2 expression and high proliferation index with Ki67 (80%) (Figures 3, 4). With the confirmed diagnosis of IVLBC, chemotherapy with R-CHOP was started. However, rituximab had to be withdrawn during the first infusion because the patient developed arterial hypotension and her hypoxemia worsened. The patient's evolution was unfavorable, with respiratory insufficiency and new neurological events, and she
